Abstract. Since the 2000s, a change in the atmospheric circulation over the North Atlantic resulting in more frequent blocking events has favoured warmer and sunnier weather conditions over the Greenland Ice Sheet (GrIS) in summer, enhancing the melt increase. This circulation change is not represented by general circulation models (GCMs) of the Coupled Model Intercomparison Project Phase 5 (CMIP5), which do not predict any circulation change for the next century over the North Atlantic. The goal of this study is to evaluate the impact of an atmospheric circulation change (as currently observed) on projections of the future GrIS surface mass balance (SMB). We compare GrIS SMB estimates simulated by the regional climate model MAR forced by perturbed reanalysis (ERA-Interim with a temperature correction of $+1.5$, $+2.5\, ^\circ \text{C}$ at the MAR lateral boundaries) over 1980–2016 to projections of the future GrIS SMB from MAR simulations forced by three GCMs over selected periods for which a similar temperature increase of $+1.5$, and $+2\, ^\circ \text{C}$ is projected by the GCMs in comparison to 1980–1999. Mean SMB anomalies produced with perturbed reanalysis over the climatologically stable period 1980–1999 are similar to those produced with MAR forced by GCMs over future periods characterised by a similar warming over Greenland. However, over the 2 last decades (2000–2016) when an increase in the frequency of blocking events has been observed in summer, MAR forced by perturbed reanalysis suggests that the SMB decrease could be amplified by a factor of 2 if such atmospheric conditions persist compared to projections forced by GCMs for the same temperature increase but without any circulation change.

1 Introduction

Starting in the late 1990s, the surface mass balance (SMB, i.e. the difference between mass sources and sinks at the surface) of the Greenland Ice Sheet (GrIS) has been decreasing through a rise in surface meltwater run-off (RU) (Fettweis et al., 2013a; van den Broeke et al., 2016). Since the 2000s, multiple melting records have been broken over the GrIS (Tedesco et al., 2013; Hanna et al., 2014; Fettweis et al., 2017) and 70% of this melt increase can be attributed to an atmospheric circulation change gauged through a shift in the summer North Atlantic Oscillation (NAO) index to negative values (Fettweis et al., 2013b). These changes have favoured anticyclonic conditions (i.e. more frequent blocking events) in summer over Greenland which enhance the melt–albedo feedback through three main ways (Box et al., 2012): (1) an increase in advection of warm air along the western coast of the ice sheet enhancing the surface sensible heat flux and thus strengthening snow grain metamorphism and further decreasing surface albedo (Tedesco et al., 2016); (2) a decrease in snowfall (SF) rates in summer leading to longer exposure of bare ice at the GrIS margins (Noël et al., 2015); and (3) an increase in incoming radiation resulting in more surface heating. For this last feature, the debate about the contribution of shortwave and longwave radiation is still ongoing as the role of clouds is opposite between the ablation zone (more sensitive to shortwave anomalies) and the accumulation zone (more sensitive to longwave anomalies). Hofer et al. (2017) point out the importance of increasing incoming solar radiation while other studies allocate the increase in surface heating and melting to longwave radia-
tion notably due to the transport of water vapour (Neff et al., 2014; Bonne et al., 2015) and liquid low-level clouds (Ben- 
nartz et al., 2013). These processes reduce meltwater refreez-
ing and then enhance meltwater RU (Van Tricht et al., 2016).

Such an amplification in surface melt is well represented by
regional climate models (RCMs) forced by climate reana-
ysis, which capture the current circulation change (Ettema et al., 2009; Fettweis et al., 2011, 2017; Noël et al., 2015, 2018). However, as general circulation models (GCMs) do not presently predict any future circulation change (Belle-
flammé et al., 2012; Fettweis et al., 2013b; Hanna et al., 2018), the melt increase currently observed is underestimated
when RCMs are forced by GCM scenarios starting from the
2000s (e.g. Fettweis et al., 2011, 2013b; Rae et al., 2012).
This raises the question of how RCM-based projections of
future GrIS SMB are affected by the GCM forcing if the re-
cent shift to negative NAO phases in summer persists through
the next decades?

To address this issue, we use the Modèle Atmosphérique
Régional (MAR), especially developed for polar regions, to
perform a sensitivity study based on the analysis of MAR-
derived GrIS SMB anomalies resulting from various forcing
experiments with ERA-Interim reanalysis and three GCMs
from the CMIP5 database (Climate Model Intercomparison
Project Phase 5; Taylor et al., 2012).

2 Data and methodology

2.1 The regional climate model MAR

The model MAR is a RCM specifically developed for sim-
ulating polar climate specificities (e.g. Amory et al., 2015;
Gallée et al., 2015; Lang et al., 2015) and furthermore abun-
dantly evaluated over the GrIS (e.g. Fettweis et al., 2011, 2017). In this study, we use version 3.8 of MAR and refer
to Fettweis et al. (2017) for a more detailed description of
MAR. Relative to version 3.5 used in Fettweis et al. (2017)
and in addition to the usual bug fixes and improved computa-
tion efficiency, the main improvement of MAR v3.8 consists
of an increase in the cloud lifetime, partly correcting the un-
derestimation of downward longwave radiation and the over-
estimation of inland precipitation described in Fettweis et al.
(2017).

MAR requires prescription of atmospheric fields (tem-
perature, specific humidity, wind speed, pressure) at its lat-
eral boundaries as well as sea surface conditions (SSC, de-
defined as sea ice concentration and sea surface temperature)
from climate reanalysis or GCM outputs. Using the ERA-
Interim reanalysis (Dee et al., 2011) to force MAR, Fettweis
et al. (2013a) have shown that the period 1980–1999 is char-
terised by a stable climate and general circulation over
Greenland, before a circulation shift occurred in summer at
the end of the 1990s. In this study, we thus consider the pe-
riod 1980–1999 as a reference (Fettweis et al., 2013a) and
discuss mean GrIS annual SMB anomalies with respect to
this reference period.

2.2 Forcing experiments

We performed two sets of sensitivity experiments according
to the large-scale forcing used, as described below.

2.2.1 ERA-Interim forcing

MAR was first forced by the ERA-Interim reanalysis every
6 h at a spatial resolution of 25 km over 1979–2016. Two dis-

tinct periods are considered: the reference period 1980–1999
and the period 2000–2016 for which a different atmospheric
circulation has been observed in summer on average by com-
parison with the reference period (Fettweis et al., 2013b, 2017; Hanna et al., 2018). Then we performed sensitivity ex-
periments in which ERA-Interim atmospheric temperatures
were increased by +1, +1.5, and +2 °C at each of the 24
vertical sigma levels of the MAR atmospheric lateral bound-
aries (hereafter referred to as perturbed reanalysis). The
mean SMB anomalies of these sensitivity experiments are
referred to as MARera+1, MARera+1.5, and MARera+2 for
anomalies averaged over 1980–1999 and MARera2k, MAR-
era2k+1, MARera2k+1.5, and MARera2k+2 for correspon-
ding anomalies averaged over 2000–2016 (Appendix A, Ta-
ble A1). Note that the relative humidity at the lateral bound-
aries was conserved by modifying the specific humidity ac-
cording to temperature changes in order to obtain precipita-
tion fields consistent with warmer ERA-Interim atmospheric

temperatures. However, SSC from ERA-Interim reanalysis
remained unchanged in the sensitivity experiments.

2.2.2 GCM forcing

We performed three additional experiments in which MAR
was forced over 1980–2060 with three GCMs from the
CMIP5 database, using the historical scenario over 1980–
2005 and the future RCP4.5 scenario (Moss et al., 2010)
over 2005–2060. Then, for each GCM, three 20-year pe-
riods (different for each GCM) characterised by a climate
about +1, +1.5, and +2 °C warmer on average than the
circulation over the reference period (as represented by the
GCM) of 1980–1999 were considered (Table 1). The differ-
ences between the GCM periods are only due to the tim-
ing required to reach each relative warming. Note that each
warming was computed as the mean JJA (June–July–August)
temperature anomaly compared to 1980–1999 over the com-
putational domain (100–0 °W, 55–85 °N) at four vertical levels
in the free atmosphere (850, 700, 600, and 500 hPa).

The three GCMs used are CanESM2, NorESM1, and
MIROC5, identified in Fettweis et al. (2013b) as the CMIP5
GCMs best representing the general circulation at 500 hPa
(influencing the precipitation amount and pattern simulated
by MAR) and the JJA temperature at 700 hPa over Greenland
(influencing the melt amount simulated by MAR) compared

The Cryosphere, 12, 3409–3418, 2018
www.the-cryosphere.net/12/3409/2018/
to ERA-Interim over 1980–1999. However, some discrepancies remain between MAR forced by these GCMs and MAR forced by ERA-Interim over 1980–1999. For instance, MAR underestimates RU and overestimates SF when forced by NorESM1 compared to MAR forced by ERA-Interim (Fettweis et al., 2013a). This is also confirmed by a recent study comparing melt energy budgets from MAR forced by ERA-Interim, MIROC5, NorESM1, and CanESM2 (Leeson et al., 2018). This is why the SMB obtained with perturbed reanalysis cannot be directly compared to the SMB obtained with GCM forcing data because of these divergences over the reference period.

Therefore we compare anomalies of these GCM-forced projections during the 20-year future periods of ∼ +1, ∼ +1.5, and ∼ +2 °C to the corresponding GCM-forced MAR climate over the reference period (1980–1999) and not directly to MAR forced by ERA-Interim over 1980–1999. As for the sensitivity experiments using the ERA-Interim reanalysis as forcing, the mean SMB anomalies associated with these GCMs experiments are respectively referred to as MARcan+x for CanESM2, MARmir+x for MIROC5, and MARnor+x for NorESM1, where x equals 1, 1.5, or 2 corresponding to a warming of +1, +1.5, or +2 °C (Appendix A, Table A2). Contrary to ERA-Interim-forced experiments, no humidity correction has been applied at the MAR lateral boundaries and the SSC are directly prescribed from the RCP4.5 scenario projected by the respective GCM.

### 3 Results

#### 3.1 Analysis of warming experiments without circulation change

Before assessing the impact of the current circulation change on SMB projections, we evaluate analogies between MAR forced by perturbed reanalysis and by GCM scenarios over future periods experiencing a similar warmer climate. Figure 1 shows the difference in SMB anomalies between MARera+1 (+2) and MARmir+1 (+2, using MIROC5 as a forcing) over 1980–1999 when the mean general circulation in summer is similar in both ERA-Interim and the GCMs. Even if the differences are mainly not statistically significant (i.e. lower than the inter-annual variability in the simulation of MAR forced by unaltered ERA-Interim over 1980–1999), the RU anomalies are generally higher if MAR is forced by GCMs rather than by corresponding perturbed reanalysis. GCM-forced simulations also predict a higher precipitation increase along the south-east of the ice sheet. These weak differences are caused by the SSC, which were not modified in experiments based on perturbed reanalysis, while the GCM-forced simulations use future SSC. Anomalies at the ice sheet margins (Fig. 1) are similar to the SMB anomalies found by Noël et al. (2014), who evaluated the (insignificant) impacts of SSC on the SMB of the GrIS. We therefore assume that anomalies between MARera+x and MARmir (or MARnor or MARcan) result from the SSC unchanged in MARera+x. Because GCMs fail to represent the circulation change observed in summer over Greenland since the 2000s, MAR forced by perturbed reanalysis over 1980–1999 simulates SMB anomalies similar to MAR forced by GCMs over the corresponding future warmer periods. Therefore, evaluating MAR forced by perturbed reanalysis over 2000–2016 allows us to evaluate the likely impact of a warmer climate induced by an increase in blocking events (as currently observed) on the projected GrIS SMB.

#### 3.2 Influence of a potential future circulation change

Over 2000–2016, the JJA temperature in the ERA-Interim reanalysis has increased by 0.7 °C in the free atmosphere (mean 850–500 hPa temperature integrated over the computation domain) compared to 1980–1999. This offset in temperature has to thus be taken into account when comparing the anomalies of the different warming experiments. The SMB anomaly MARera2k+1 (MARera2k+1.5) is significantly more negative (up to a factor of 2) than perturbed-reanalysis experiments and GCM-forced future experiments relative to a climate warmer by +1.5 °C (+2 °C) (Table 2). This suggests that capturing the recent circulation change simulated by perturbed-reanalysis experiments would enhance the projected SMB decrease compared to the decrease projected for a warmer climate without any circulation change. This is illustrated in Fig. 2 in which the decrease
in SMB is amplified for an equal increase in temperature of +2 °C over 2000–2016 (Fig. 2b), i.e. including the recent circulation change, compared to the decrease for the reference circulation over 1980–1999 (Fig. 2a). Additional 2-D representations of these differences for GCM experiments are available in the Supplement.

As RU and SF mainly drive the GrIS SMB (Box et al., 2004), we mainly discuss in the following the anomalies relative to these two components. As for SMB anomalies, RU and SF anomalies are computed as differences between the corresponding mean value for a given experiment and the mean value for the reference period using the unaltered large-scale forcing (Table 2). Even though non-significant, an increase in SF is observed for all experiments associated with a rise in temperature in response to a higher air capacity for holding water vapour (Fettweis et al., 2013a). Moreover, mean RU anomalies increase with the temperature rise in all warming experiments, most significantly for the experiments using perturbed reanalysis over 2000–2016 when the circulation change has occurred. It can thus be concluded that run-off is mainly responsible for the SMB discrepancies between the different sensitivity experiments in a warmer climate. As for RU, melt anomalies are also amplified with the circulation change (Table 2). However, RU anomalies are systematically higher than melt anomalies. This can be explained by two factors (Machguth et al., 2016): (1) there is less pore place available for meltwater storage in warmer and then more saturated firn and (2) the bare ice area (in the ablation zone) is larger in a warmer climate, reducing the potential surface for meltwater storage, which also amplifies the meltwater run-off increase. The future decrease in the ice sheet meltwater retention capacity has notably been discussed by Van Angelen et al. (2013).

On average over the ice sheet, downward shortwave radiation (SWD) and downward longwave radiation (LWD) are respectively almost 4 and 3 W m$^{-2}$ higher over the 2000–2016 period than over the reference period (Table 3). This is in concordance with the conclusions of Hofer et al. (2017), which argue that the current observed melt increase since the 2000s is a combination of the increase in SWD and LWD. However both simulations forced by perturbed reanalysis and in GCM-forced simulations with a warmer climate suggest a strong SWD decrease as a result of an increasing cloud cover, as already discussed in Franco et al. (2013). This effect combined with a higher free-atmosphere temperature explains then the increase in LWD in a warmer climate (Hofer et al., 2017).

Due to the enhanced positive melt–albedo feedback since the 2000s, SWD absorbed by the surface is more than 2 times higher in simulations with perturbed reanalysis over 2000–2016 than over the reference period. Due to a lower albedo (in particular in the ablation zone), the surface absorbs more energy, amplifying the melt increase, which further decreases the albedo, potentially re-accelerating melting in addition to a decrease in the ice sheet capacity to refreeze meltwater. This positive feedback triggered by more frequent anticy-
Figure 2. (a) Mean anomalies of annual SMB (mm w.e. y\(^{-1}\)) of MAR forced by an ERA-Interim warmer by +2 °C compared to MAR forced by unaltered ERA-Interim over 1980–1999. (b) Differences between mean anomalies of annual SMB (mm w.e. y\(^{-1}\)): MARera2k+2 minus MARera2k. Areas where anomaly differences are smaller than the inter-annual variability (i.e. the standard deviation) of the simulation of MAR forced by unaltered ERA-Interim over 1980–1999 are hatched. Dashed lines are equal altitude lines of 2000 and 3000 m. See Appendix A and Tables A1 and A2 for abbreviations.

Table 2. Mean GrIS-integrated anomalies of annual SMB (Gt y\(^{-1}\)), RU (RU), snowfall (SF), and melt (ME) compared to 1980–1999. Anomalies from GCM-forced simulations are given as averaged. Anomalies greater than the 1980–1999 standard deviation (i.e. greater than the inter-annual variability) of the simulation of MAR forced by unaltered ERA-Interim are shown in bold.

clonic summer situations over Greenland causes a run-off increase nearly 2 times higher in simulations over 2000–2016 than in the simulations over the reference period.

In the absence of a circulation change, the increase in near-surface temperature (T2m) is only due to the temperature increase prescribed at the MAR lateral boundaries (Table 3). With a circulation change, the increase in T2m is higher and no more uniform as a result of enhanced warm air advection along the West GrIS (see Fig. S1 in the Supplement). Such more frequent anticyclonic conditions, resulting from more frequent blocking events (Hanna et al., 2018), explain the increase in cloud cover at the north of the ice sheet and the associated LWD increase shown in Hofer et al. (2017) in this area, while sunnier conditions dominate in the southern part.

4 Conclusions

The goal of this study is to assess the impact of unresolved recent atmospheric circulation change in GCMs on RCM-based projections of future GrIS SMB. For this purpose, we used the RCM MAR and performed forcing sensitivity experiments with the ERA-Interim reanalysis and large-scale fields from three selected GCMs of the CMIP5 database to investigate the influence of a warmer atmosphere in the context of a circulation change inducing more frequent blocking events.

We used the annual SMB produced with each original forcing over the climatologically stable period of 1980–1999 as a reference to compute mean annual SMB anomalies relative to each forcing experiment.

The first experiments consisted of increasing the atmospheric temperature in the ERA-Interim reanalysis by +1, +1.5, and +2 °C at the MAR lateral boundaries over two distinct periods, i.e. 1980–1999 and 2000–2016, respectively before and after the shift in the summer NAO index. Additional forcing experiments were then performed using the three selected GCMs to force MAR over the reference period and over 20-year future periods for which a similar temperature increase of ∼+1, ∼+1.5, and ∼+2 °C is predicted by these GCMs in the free atmosphere.

The comparison among SMB anomalies relative to perturbed reanalysis and GCM future experiments revealed similar results for each corresponding warming experiment, since for each GCM the atmospheric circulation remains unchanged over time. This allowed us to evaluate the likely impact of a warmer climate induced by a circulation change on the GrIS SMB by comparing SMB anomalies relative to perturbed reanalysis over 2000–2016 with GCM-forced future SMB anomalies. This comparison suggests that capturing the circulation change leads to SMB anomalies 2 times higher on average with a circulation change than without for a similar atmospheric warming. These higher anomalies are explained

by more frequent summer anticyclonic situations over GrIS, leading to an increase in SWD and warm air advection along the west coast, both promoting a decrease in albedo. As a result, the run-off increase is enhanced and is responsible for the higher decrease in SMB.

The results of this study suggest that previous estimates of GrIS melt projections produced using CMIP5 data as forcing (e.g. Rae et al., 2012; Fettweis et al., 2013a) could be significantly underestimated if the current summer atmospheric circulation pattern over Greenland persists. In the context of the forthcoming sixth phase of the Coupled Model Intercomparison Project, our conclusions highlight the importance of examining whether GCMs predict circulation changes in the next decades and, if so, of evaluating their potential influence on projections of the future GrIS SMB. Another remaining scientific challenge of particular interest for GrIS SMB projections is to establish if the increasing frequency of blocking events could be linked to global climate change.

Data availability. All MARv3.8 outputs presented here are available upon request by email (alison.delhasse@uliege.be), and the source code of MARv3.8 is available at ftp://ftp.climato.be/fettweis/MARv3.8/src/ (Fettweis et al., 2017). The ECMWF reanalyses (ERA-Interim) were downloaded from http://apps.ecmwf.int/datasets/.

The Supplement related to this article is available online at: https://doi.org/10.5194/tc-12-3409-2018-supplement

Author contributions. AD and XF conceived the study. AD and XF performed the simulations. AD led the writing of the manuscript. AD, XF, CK and Cha discussed the results. All co-authors revised and contributed to the editing of the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. Computational resources have been provided by the Consortium des Équipements de Calcul Intensif (CÉCI), funded by the Fonds de la Recherche Scientifique de Belgique (F.R.S.-FNRS) under grant no. 2.5020.11 and the Tier-1 supercomputer (Zenobe) of the Fédération Wallonie Bruxelles infrastructure funded by the Wallonia region under the grant agreement no. 1117545. Finally, we would like to thank the two anonymous reviewers for their constructive remarks that helped to improve the paper.
